Abstract

When Wave Function Collapse (WFC) was released, it took the Procedural Content Generation by storm. From games [1]–[3] to poetry [4] and music [5], [6], WFC has seen application across a huge number of fields. However, many implementations available online suffer from issues like a lack of global constraints as well as poor performance and documentation.

This project contextualises WFC within theory of constraint programming and implements simple-tiled WFC using the Maintaining Arc Consistency 3 algorithm. WFC is extended to generate infinite worlds using Infinite Modifying in Blocks [7]. An interface is provided for the Unity Editor that allows designers to specify their own tile set to use for generation. As example, a tile set themed after the popular fictional concept of ‘the Backrooms’ is created.

With additional time, the solver could be optimised to use multi-threading and lazy loading to improve performance. Furthermore, the Unity Editor interface could be polished to make it easier to specify tile sets. Finally, the Backrooms game demo could be extended through additional models, puzzles and levels.

Declaration

I declare that the material submitted for assessment is my own work except where credit is explicitly given to others by citation or acknowledgement. This work was performed during the current academic year except where otherwise stated.

The main text of this project report is XXXXX words long, including project specification and plan.

In submitting this project report to the University of St Andrews, I give permission for it to be made available for use in accordance with the regulations of the University Library. I also give permission for the title and abstract to be published and for copies of the report to be made and supplied at cost to any bona fide library or research worker, and to be made available on the World Wide Web. I retain the copyright in this work.

Acknowledgements

I would like to thank all those who supported me throughout the time of the project, from university staff to family and friends.

Chapter 1

Introduction

Wave Function Collapse (WFC) is a Procedural Content Generation (PCG) technique that has found significant use in video games [8]. WFC can be described as a family of algorithms that enable generation of large game worlds from limited input through the application of constraint programming principles [9].

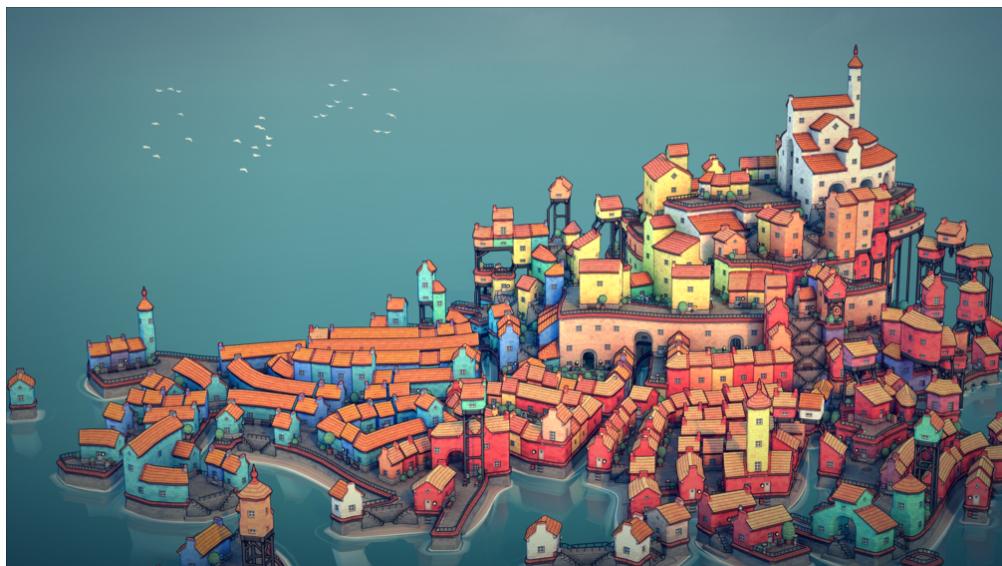

Figure 1.1: Townscaper uses WFC with player input to develop worlds [1]

This dissertation applies the simple tiled implementation of WFC. In simple tiled WFC, a tile set with adjacency information is used by a constraint solver. This solver attempts to fill a grid of cells with tiles, taking into account their constraints. In the rest of this dissertation, this simple tiled implementation of WFC is simply referred to as the WFC algorithm.

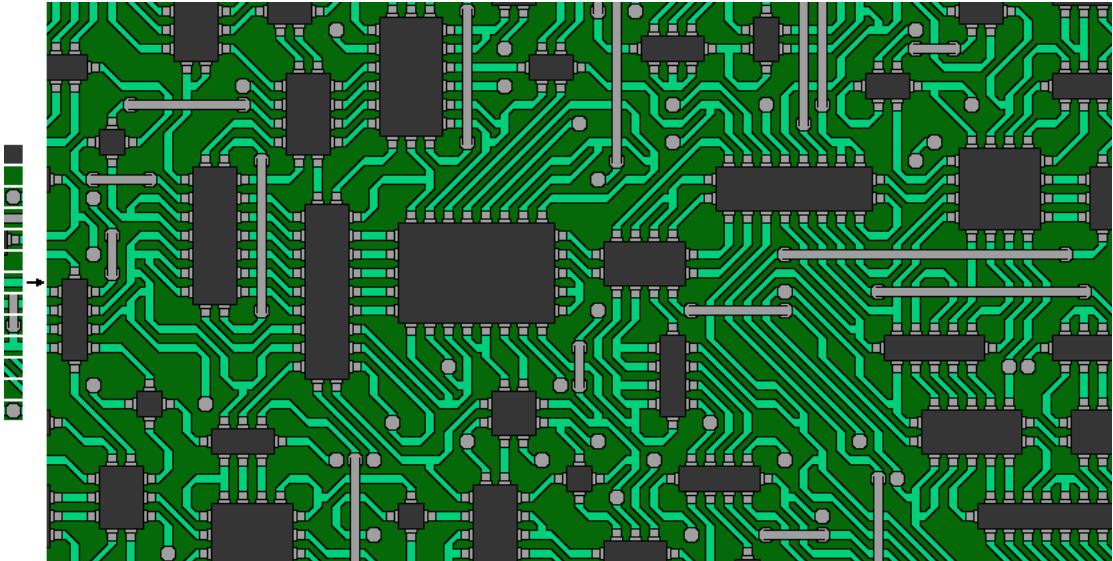

Figure 1.2: Use of simple tiled WFC to generate a circuit board graphic [8]

WFC's application is commonly limited by its lack of global constraints, overfitting and performance. Lack of global constraints can result in no inherent overall structure to the output, making it homogeneous. Use of complex tile sets can result in overfitting, reducing output variety. Complex tile sets and large grids also result in poor performance and increased failure rate.

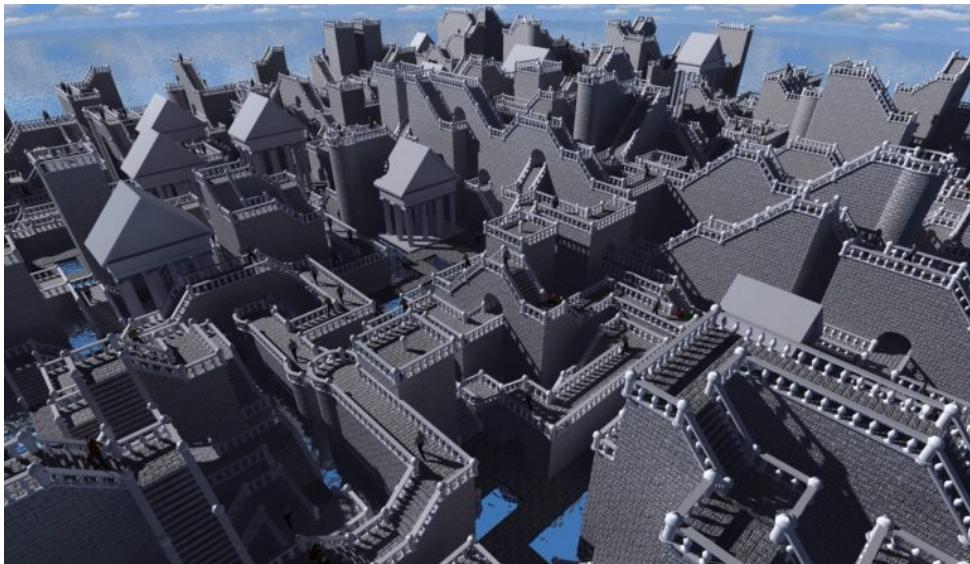

Figure 1.3: A complex Escheresque tile set that relies on modifying in blocks [10]

These issues are rarely addressed directly in implementations. Instead, they are worked around in an ad hoc, game-specific way that fails to exploit constraint programming techniques.

Presentation of WFC online often fails to acknowledge underlying constraint solving principles used by WFC. Instead, alternative wording is used, which can make forming a deep understanding of the topic challenging. This dissertation draws an explicit connection between WFC and the Maintaining Arc Consistency 3 (MAC3) algorithm, presenting an implementation in those terms.

This dissertation's WFC implementation is extended using the Infinite Modifying in Blocks (IMIB) algorithm, which addresses the challenge of extending WFC to an infinite space. Furthermore, an interface integrated into the Unity game engine for designers to use WFC on their own tilesets is included and a simple game created as example.

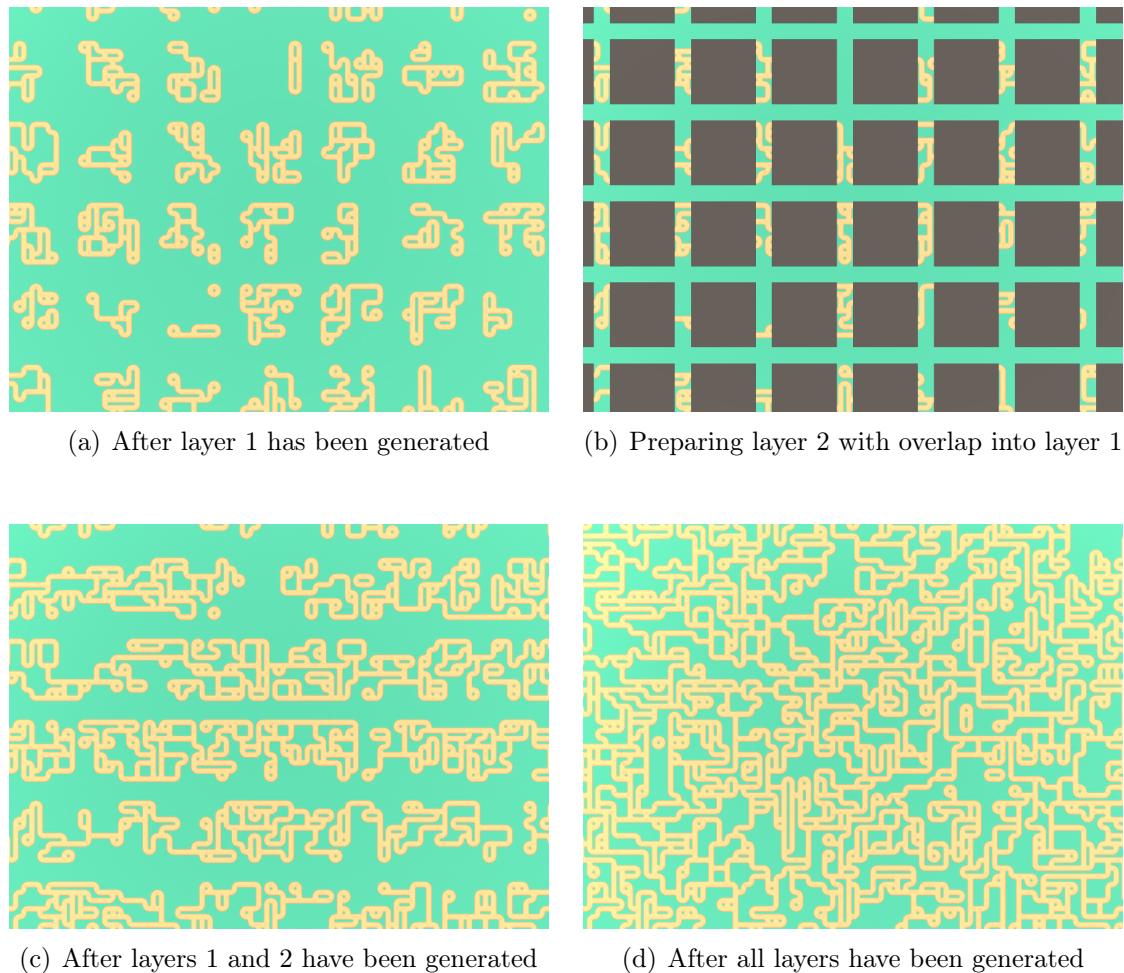

Figure 1.4: A glimpse into the IMIB pipeline. Each layer defines a small part of each chunk to run WFC in. By clearing and running four overlapping layers, a full grid is generated. [7]

Chapter 2

Player Guide

Premise

Embark on an infinite journey through the enigmatic depths of the Backrooms. Take in the eerie solitude in this procedurally generated liminal space, where the boundaries between reality and the unknown blur into obscurity. Scavenge for any items left behind and piece together an escape at the elusive escape points scattered throughout. Will you manage to find an exit, or will you become lost forever in this maze of yellow hues and buzzing lights?

Chapter 3

Literature Review

Three key themes identified to be investigated were constraint programming, wave function collapse and procedural content generation. While these themes are presented in three different sections, the ideas discussed heavily overlap.

Constraint programming and procedural content generation have wide applications and have been a big area of recent research. For example, procedural content generation has seen an increased use of machine learning in recent years, allowing new content to be generated from large dataset models. Similarly, novel constraint programming techniques such as wave function collapse have seen use in generating new output from very limited input data. These techniques are typically applied to video games in order to help create an ever changing experience for the player.

3.1 Constraint Programming

3.1.1 Overview

Constraint programming deals with modelling problems through constraints and then running a solver to find solutions. In the context of PCG and video games, the use of constraints can be useful to tailor the output of PCG as desired and generate new content based on old content. Constraint programming has also been used to solve game tasks. The use of constraints allows for well-defined outputs to be created, but pay for this with more unpredictable generation times when compared to other methods [11].

Constraint programming has been applied to a large variety of problem categories, ranging from combinatorial mathematics to logistics and scheduling [12].

3.1.2 Combinatorial Problems

For example, three papers take a deeper look into combinatorial problems, which deal with finding an optimal solution among a finite set of possibilities. Deep reinforcement learning has been used to tackle these problems, but it only provides approximate solutions [13]. To find optimal solutions, the paper combines deep RL with constraint programming, detailing its use for problems such as the travelling salesman problem with time windows and the 0-1 knapsack problem. Large scale combinatorial problems may have huge search spaces, resulting in low solver performance [13]. To address this, it introduces and automated process to add streamliner

constraints, which focus effort on searching promising parts of the search space to improve performance. A survey of combinatorial problems and attempts at modelling and solving them effectively identifies, for example, that algorithm selection techniques can achieve significant performance improvements for combinatorial search [14]. It presents a model for the algorithm selection problem as in Figure 3.1.

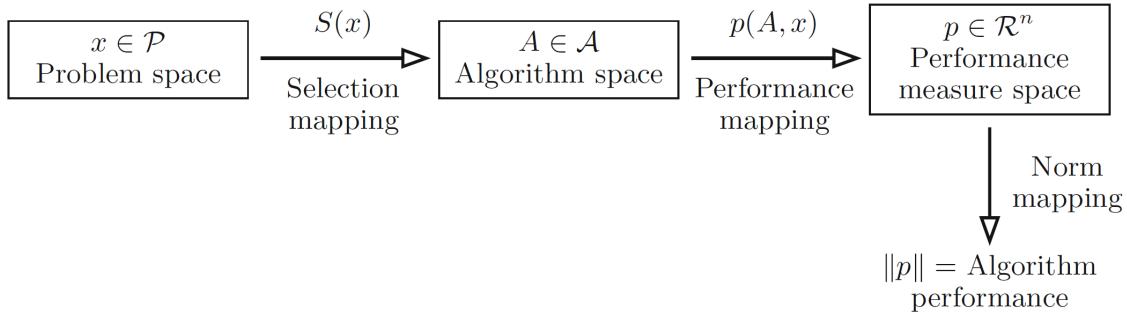

Figure 3.1: Basic model for the Algorithm Selection Problem [14]

Another paper [15] recognises the difficulty in testing constraint solvers due to the vastness of searches they may perform. As a solution, it uses metamorphic testing, which generates new test cases from existing ones. However, it expresses the limitation that this should be used with other forms of testing as metamorphic testing does not recognise when a solver falsely identifies a problem as unsolvable.

3.1.3 Logic Programming Languages

Another interesting application of constraint programming is to AI deep reinforced learning. One paper [16] explores the use of the Prolog logic programming language to generate data sets to aid this learning, finding positive results in trained AI agent performance. As part of this process, the paper converts user-specified constraints into Prolog queries through a Python program that generates JSON house plans as in Figure 3.2. The pipeline for this is shown in Figure 3.3.

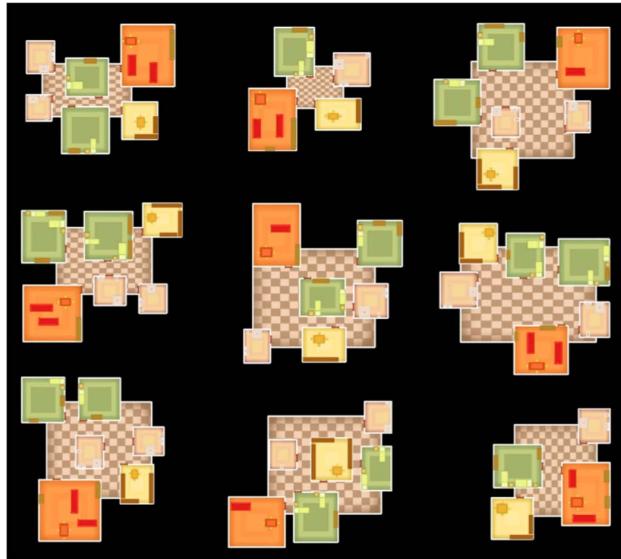

Figure 3.2: Examples of generated house plans [16]

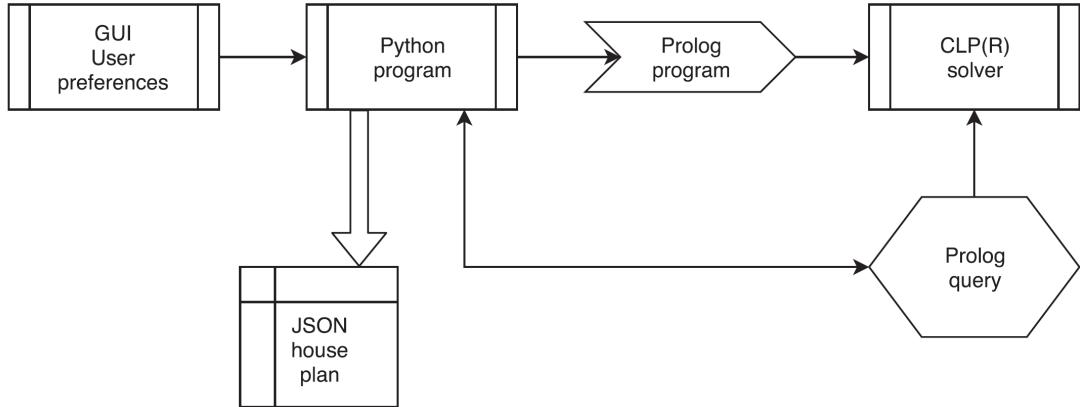

Figure 3.3: Python converting user-specified constraints into Prolog queries [16]

Other languages similar to Prolog such as Answer Set Programming (ASP) and the Video Game Description Language (VGDL) extend Prolog’s concepts with application to video games. For example, ASP can be used to generate constrained dungeons as in Figure 3.4 [17]. A range of constraints are encoded. Altars (the golden A tiles) are constrained to have four empty tiles around them. Wall tiles must have at least two neighbouring walls, encouraging the formation of larger wall segments. Gems (the green G tiles) must have three adjacent walls, making them stuck in wall segments. Finally, there must be a path with a minimum length between altars and gems, as well as a path diagonally across the level through this. All of these constraints work together to generate interesting, playable levels.

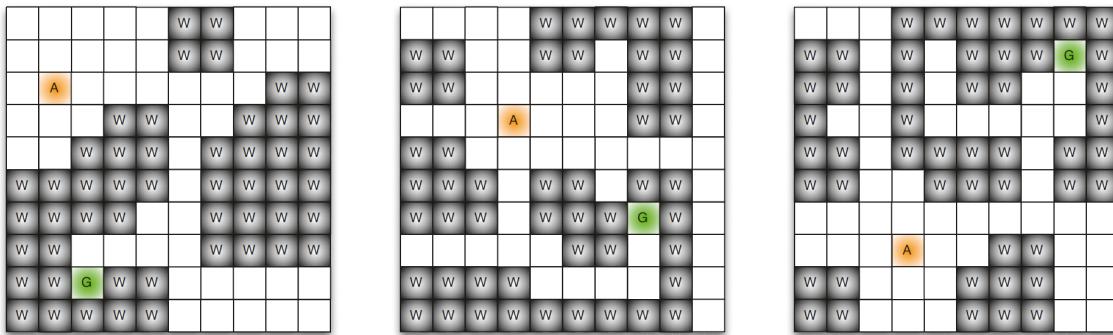

Figure 3.4: Examples of dungeons generated using ASP [17]

One paper [18] also applies constraint programming to dungeon generation, but instead uses a graph constraint to generate high quality dungeons with distinct areas. Hundreds of variations can be generated from one dungeon with labelled rooms. The dungeon is represented as a graph, which lets areas be selectively turned off and rearranged while meeting design constraints. The concept is shown in Figure 3.5.

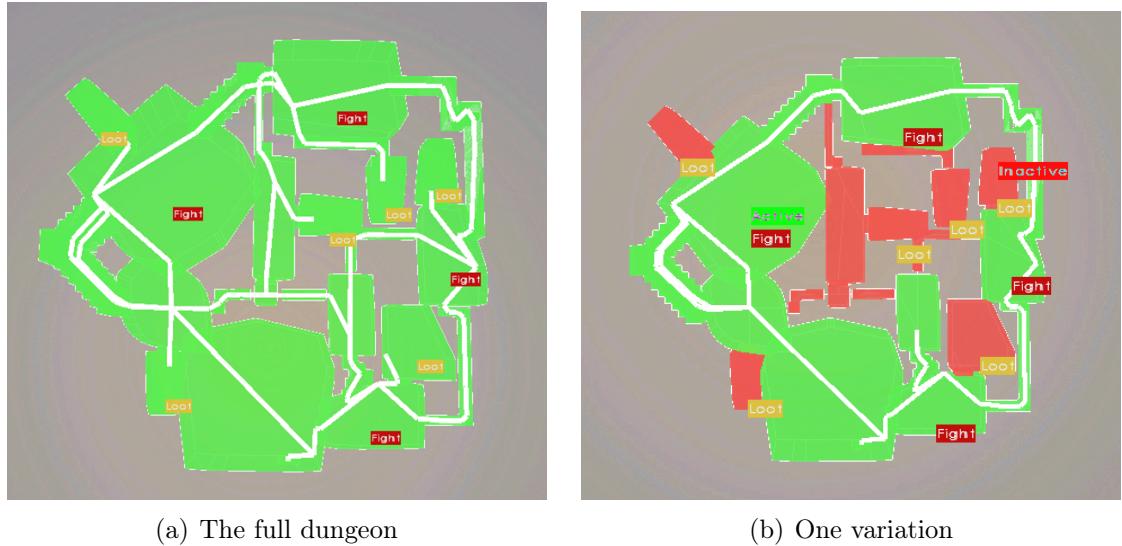

Figure 3.5: Generating a variation from a larger dungeon [18]

Another paper [19] builds on the General Video Game AI framework (GVG-AI) and the Video Game Description Language (VGDL) to create general video game generators. These generators aim to save time by eliminating the need to custom-build a generator for each game. Instead, a game description is given as input and used to generate a level for the game. The results of three generators for a Zelda-style game are shown in Figure 3.6. Here, the aim is to collect the key and get to the exit while avoiding attacks by monsters. The player has a sword which can be used to attack monsters and gain additional points.

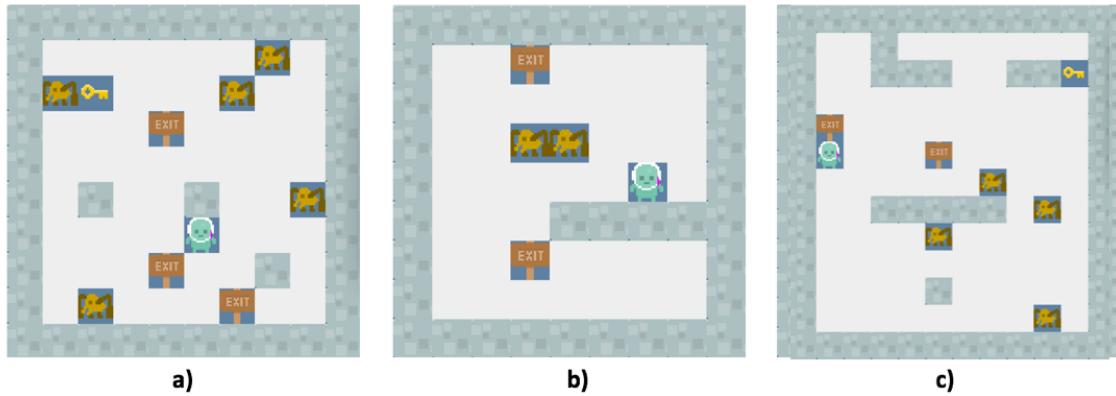

Figure 3.6: Zelda-style levels being generated by a Random Level Generator (a), Constructive Level Generator (b) and Search-Based Level Generator (c) [19]

3.1.4 Further Application to Video Games

In the context of video games, constraint programming research has looked into applying constraints to PCG and solving game tasks. One recent paper [20] aims to solve a planning problem presented in the game Plotting. In it, the player must plan a sequence of actions to clear blocks of varying types from a grid. The paper models the problem in two modelling language, namely the widely used Planning Domain Definition Language (PDDL) and the novel Essence Prime. Their effectiveness is

then compared using several solvers, finding a SAT solver to be most effective for the problem as shown in Figure 3.7.

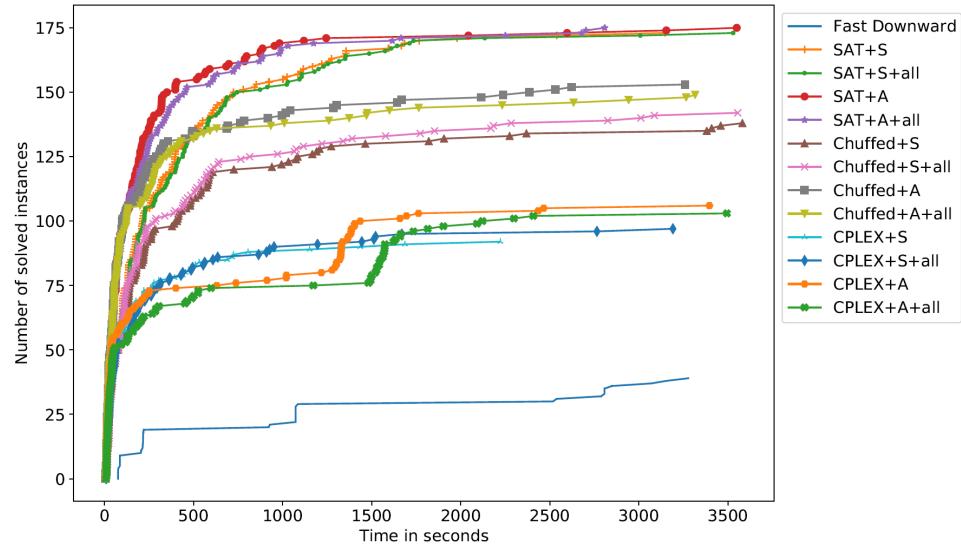

Figure 3.7: Comparing performance of Plotting models and solvers [20]

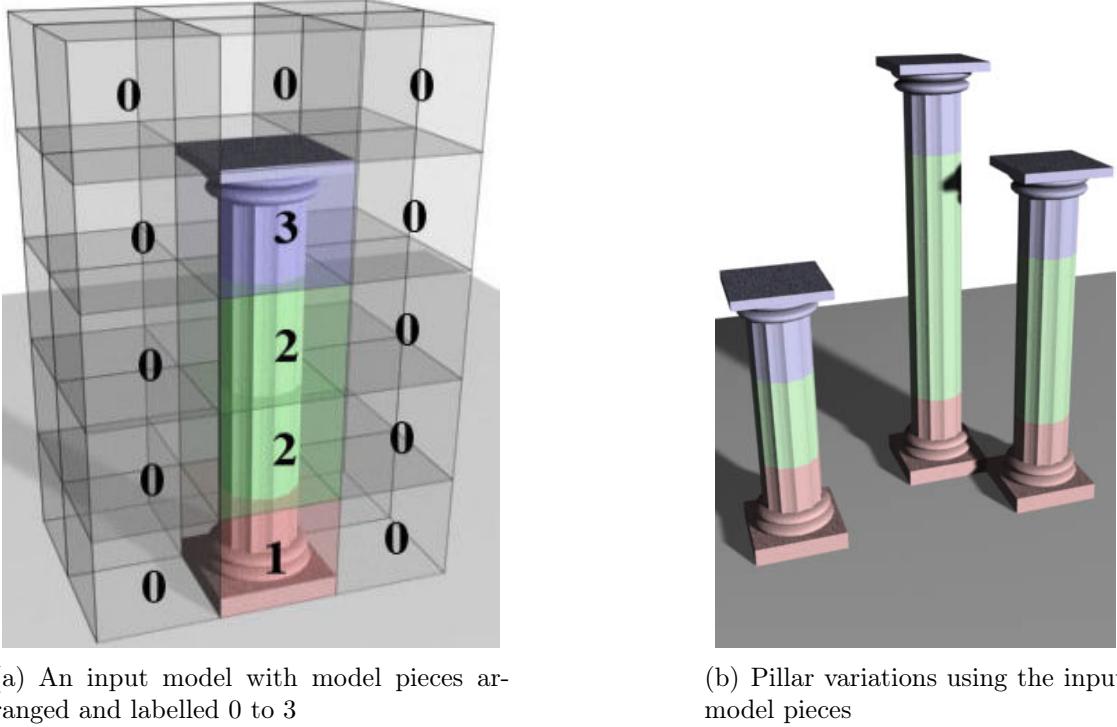

3.2 Wave Function Collapse

Wave Function Collapse (WFC) [8] is a modern PCG method that has found use in games such as Townscaper [1] and Bad North [2]. It can be described as a family of algorithms, rather than one specific algorithm [9]. As such, a large variety of implementations are available online, each with their own specialisations to solve the problem they were designed for. One paper noted that Wave Function Collapse is often used as a black box, being incorporated into a workflow without being altered [11].

Figure 3.8: Bad North uses WFC to generate islands traversable by AI [2]

Wave Function Collapse builds off of the concepts of Model Synthesis, which is a method for procedurally modelling complex 3D shapes [10], [21]. In Model Synthesis, the user defines an input model detailing various dimensional, geometric and algebraic constraints. This is then used to create output satisfying the modelled constraints. A simple example using a pillar model is shown in Figure 3.9.

(a) An input model with model pieces arranged and labelled 0 to 3

(b) Pillar variations using the input model pieces

Figure 3.9: Generating pillars of different lengths from input model pieces [10]

3.2.1 Implementation Variations

Data Input

The data input stage is likely the WFC stage with the most variation across implementations. The original implementation [8] supports both an overlapping and simple tiled model. The overlapping version takes a sample image and defines overlapping patterns of $N \times N$ tiles, where the output is constructed of a random arrangement of these patterns. The overlapping WFC pipeline is shown in Figure 3.10. The simple tiled model instead defines single tile patterns, where each tile has its own defined set of possible neighbours. An example of simple tiled generation was shown in the Introduction in Figure 1.2.

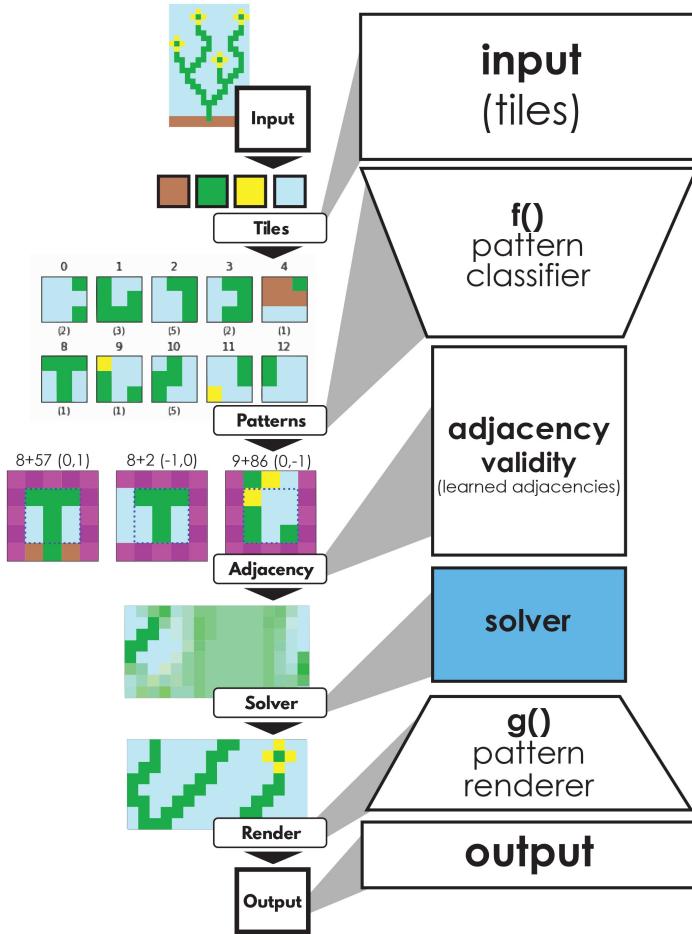

Figure 3.10: The overlapping WFC pipeline with 3×3 overlap [9]

2D vs 3D

While a lot of implementations focus solely on 2D input tiles and grids, much fewer implementations support 3D input or output. This makes it a challenge to apply WFC to 3D environments. Furthermore, the increased complexity from a 3D environment can lead to an increased failure rate, which requires techniques such as backtracking or modifying in blocks to counteract. This was highlighted in the Introduction with Figure 1.3.

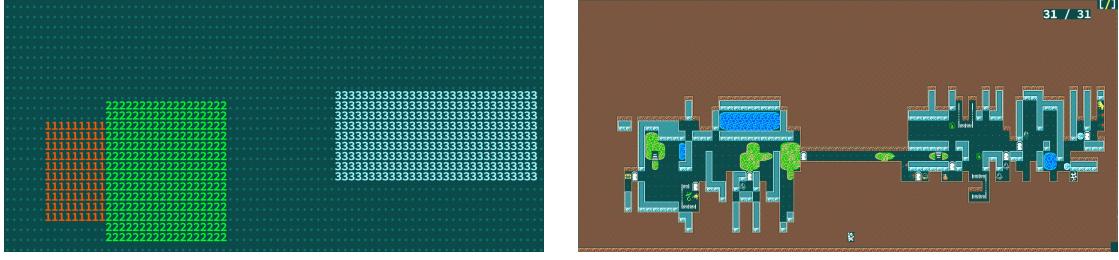

3.2.2 Limitations of Wave Function Collapse

Research papers on WFC frequently attempt to identify and find solutions for problems that implementations of the algorithm commonly face. Some of the most common problems are a lack of global constraints, overfitting and performance. These problems, as well as some other challenges, are discussed below.

Lack of Global Constraints

One problem with WFC is that, while output can be tailored to satisfy local constraints, global constraints are not inherently supported. This results in there being no inherent overall structure to the output. In other words, the output can be homogeneous.

In some applications, such as the game Caves of Qud [3], WFC is used only after other algorithms have defined distinct regions of the map as shown in Figure 3.11 [9], [22], [23]. This multi-pass approach allows WFC to be used to its strengths.

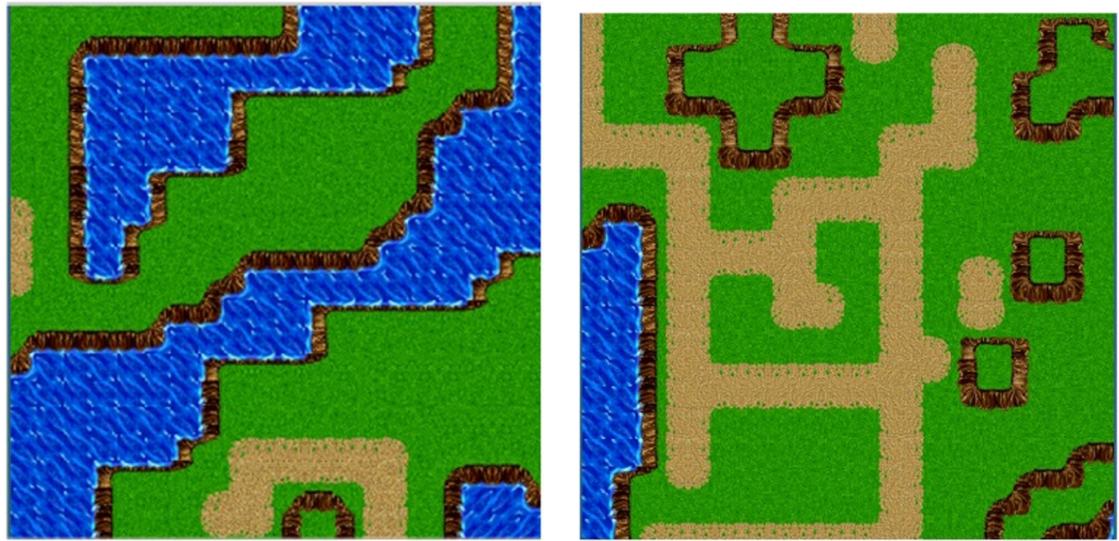

(a) Areas of the level set before using WFC (b) Interiors generated using WFC

Figure 3.11: Caves of Qud’s multi-pass approach to avoid homogeneity [23]

Two papers add in additional constraints that are checked after each observation step. In the first paper [24], constraints added include a minimum tile count, maximum tile count and object distance constraint.

The global maximum tile count constraint allows balancing of tile counts. This constraint is analogous to the use of weighted tile selection. Figure 3.12 shows the global maximum tile count constraint being used to reduce the amount of water in the level.

(a) Generation without the maximum constraint (b) Generation with the maximum constraint

Figure 3.12: Use of the global maximum constraint to limit water tiles [24]

The global minimum tile count constraint gives more control on how tiles should be placed in the level. The way it is presented in the paper shows it being used to preset tiles before generation. This enables the definition of key areas that should be present in the output. Figure 3.13 shows the global minimum tile count constraint being used to place water in the bottom left and land in the middle of the level.

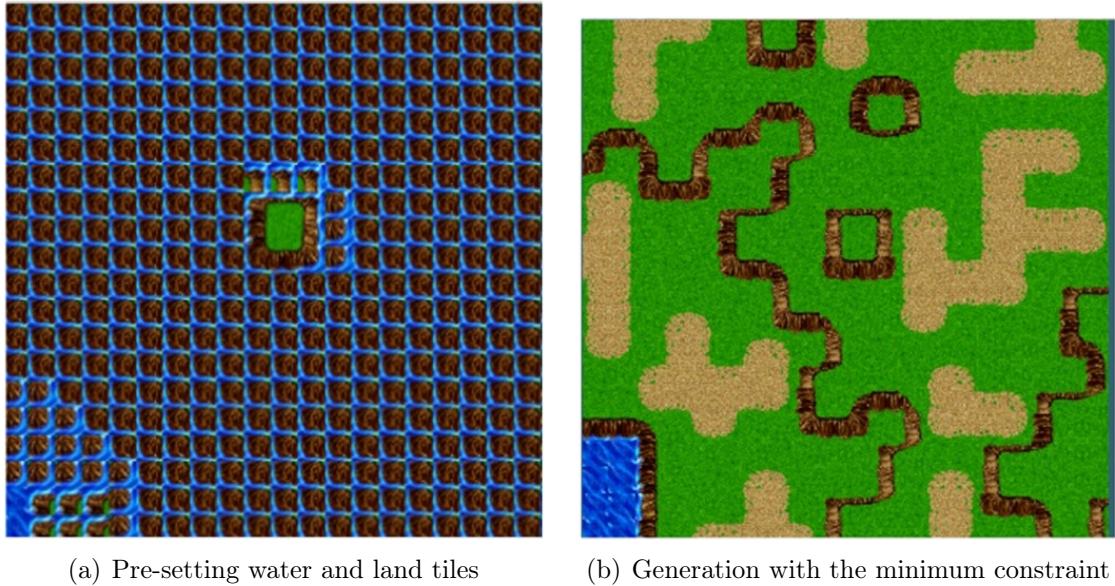

Figure 3.13: Use of the global minimum constraint to pre-place tiles [24]

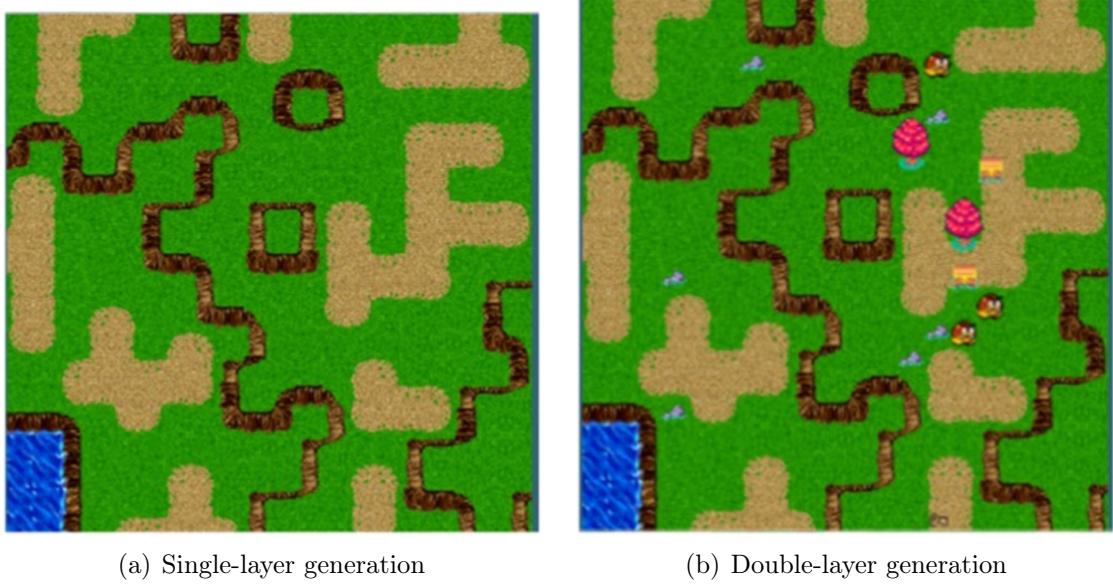

The object distance constraint is used to create areas of interest, rather than scattering items equally throughout the level. Figure 3.14(a) shows how without an object distance constraint, enemies and items are scattered at random throughout the level. In contrast, Figure 3.14(b) shows how enemies are clustered around a treasure chest. To achieve this, enemies are constrained to be less than 10 units away from chests. Furthermore, keys are constrained to be more than 10 units away from chests. This means that keys will not simply spawn next to chests, making finding them more interesting.

Figure 3.14: Use of the object distance constraint to improve object spawns [24]

One additional option included is to carry out generation in two passes. This helps create levels of certain styles and to reduce conflicts arising from trying to generate everything in one pass, such as placing an object on an unsuitable tile. In

Figure 3.15, double-layer generation is used to spawn enemies on grass and chests on dirt roads. Furthermore, rock and dirt decor is placed on suitable tiles.

(a) Single-layer generation

(b) Double-layer generation

Figure 3.15: Use of the double-layer generation to ease object spawning [24]

The second paper, [22], achieves the same goal as minimum and maximum tile count constraints through the use of a weighted choice. In addition to using entropy to choose the most constrained tile after each propagation step, assigning a weight to each choice can encourage the algorithm to choose a different balance of tiles. Furthermore, this paper introduces a second observation step. This performs a second, smaller scale WFC algorithm, which can be used to refine item placement and create subregions within a map.

Solutions altering WFC directly to support global constraints are faced with the issue that the additional constraints can have a negative impact on performance. However, by combining such solutions with those discussed in the Performance Sub-section (3.2.2), the impact can be reduced [9].

Overfitting

When adding a lot of detail to the input, such as through using complex tile sets, the output may become too constrained. This can result in overfitting and an increased failure rate.

Here, a multi-pass approach can not only be used to help globally constrain the output, but also to reduce risk of overfitting. This is done by reducing the detail of the input and instead adding additional details to the output in a second pass once WFC has run. Caves of Qud applies this approach by generating architecture using WFC and then generating details using additional passes as in Figure 3.16 [23].

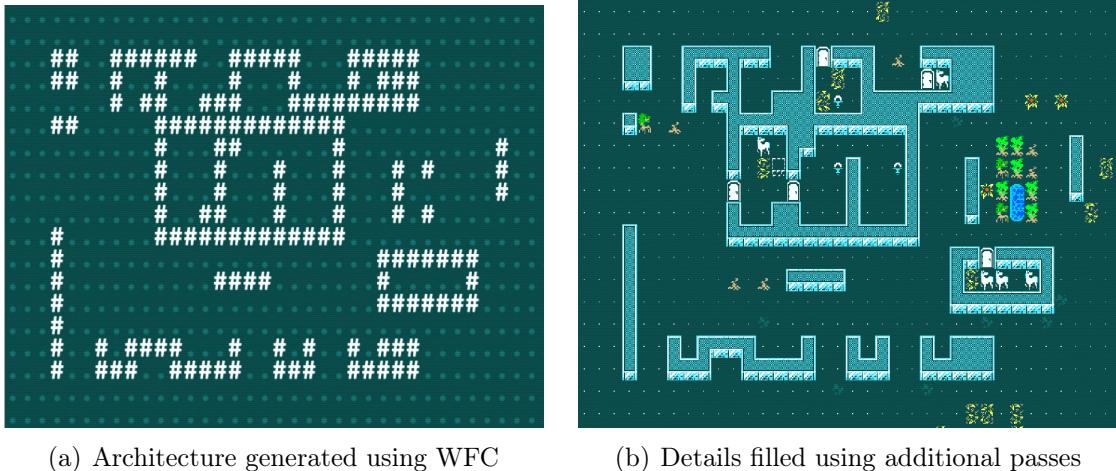

Figure 3.16: Caves of Qud’s multi-pass approach to avoid overfitting [23]

Performance

Another issue identified with WFC is performance. While the chance of success is high with small inputs, larger inputs are much likelier to fail, especially with more complicated tile sets [9]. This can result in a significant generation time for large outputs. Several solutions to WFC’s scalability problem have been proposed.

One of the most common solutions is to include some form of backtracking, which allows further searching of the search space upon a contradiction instead of having to restart. However, with complex tile sets, care must be taken to reduce the chance of backtracking exploring an unpromising search space for an extended time as in the 3D Escheresque example shown previously in Figure 1.3. Using a search heuristic could help with this. One paper compared the performance of WFC with and without backtracking and global constraints, finding that backtracking is critical to improving performance when using global constraints as seen in Figure 3.17 [9].

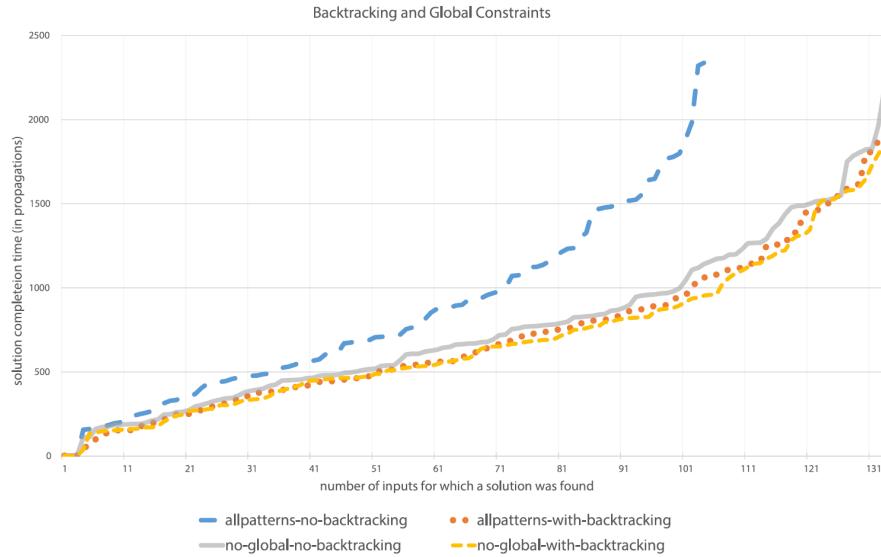

Figure 3.17: Comparing performance of WFC with and without backtracking and global constraints. When using global constraints, backtracking significantly improves performance. [9]

Nested WFC (N-WFC) [25] is one technique that aims to improve scalability of WFC. It splits a larger grid into smaller grids, evaluating sub-grids diagonally from the top left as in Figure 3.18. Each sub-grid overlaps constraints from its left and upper neighbour to satisfy constraints between adjacent sub-grids. This can be extended to an infinite space by overlapping new cells with old cells as in Figure 3.19. While this technique does improve the performance of WFC, evaluation found that that a large number of conflicts from edge data still occur.

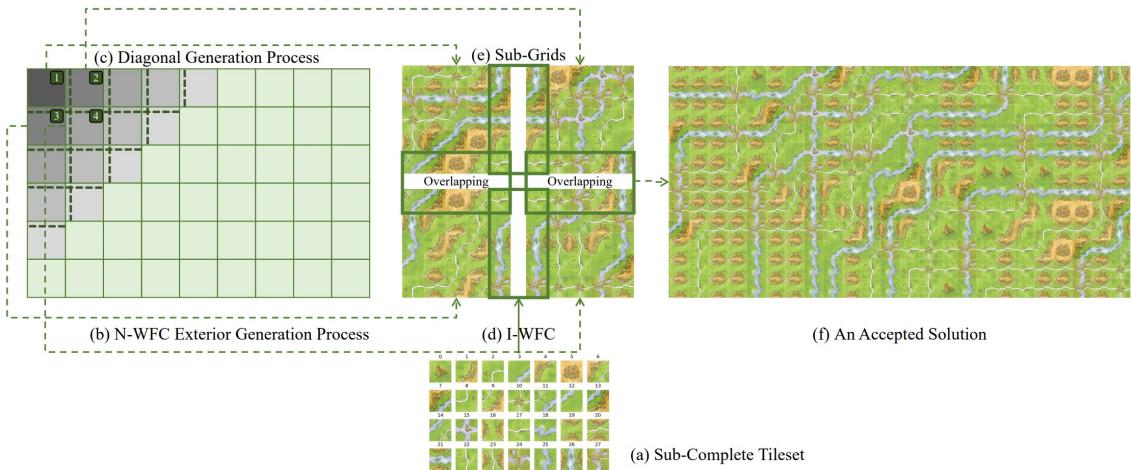

Figure 3.18: Large-scale game implementation with N-WFC and sub-complete tile set. First, it requires (a) one sub-complete tile set. Then the (b) Exterior Generation Process uses (c) Diagonal Generation Process to start generating. Each (d) sub-grid uses (e) I-WFC to find an accepted solution and overlap its edge with the adjacent sub-grids, forming an (f) final solution. [25]

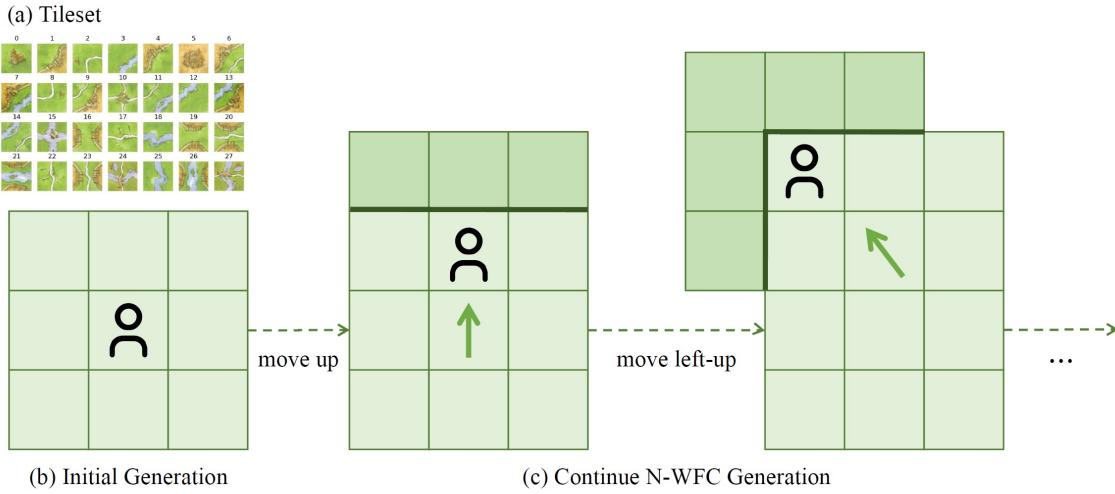

Figure 3.19: Infinite game implementation with N-WFC and sub-complete tile set [25]

Another technique, infinite modifying in blocks [7], applies WFC multiple times in small chunks. Keeping the chunks small keeps the performance of generation high, while running WFC in four layers per chunk ensures that constraints are satisfied between adjacent chunks. The layering also addresses the limitation of conflicts that Nested WFC struggles with. As each chunk is made up of four WFC layers, failed layers can usually be ignored rather than having to be regenerated. However, this comes with computational overhead from running WFC four times per chunk. An overview of the method was shown in Figure 1.4.

Other Challenges

Environments of a certain style, especially those trying to create a realistic feel, may struggle from WFC's use of a grid structure for its output. However, if this regular grid is transformed into an irregular quadrilateral grid, more complex shapes can be used.

One paper [26] achieves this by using a graph-based data structure, which can be integrated with a navigation mesh in 3D as shown in Figure 3.20. However, this solution is limited due to a lack of control over solution order.

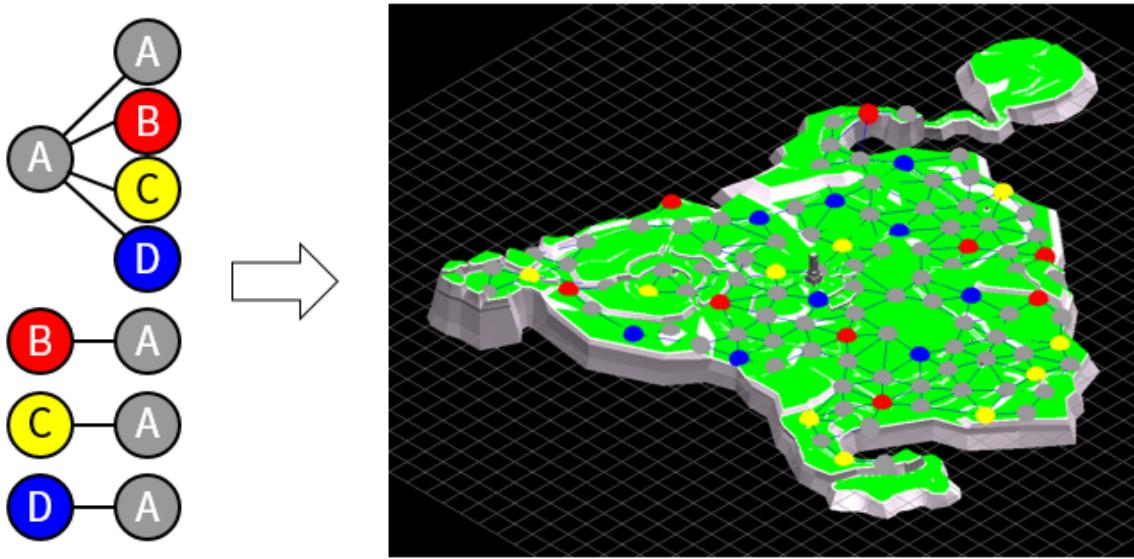

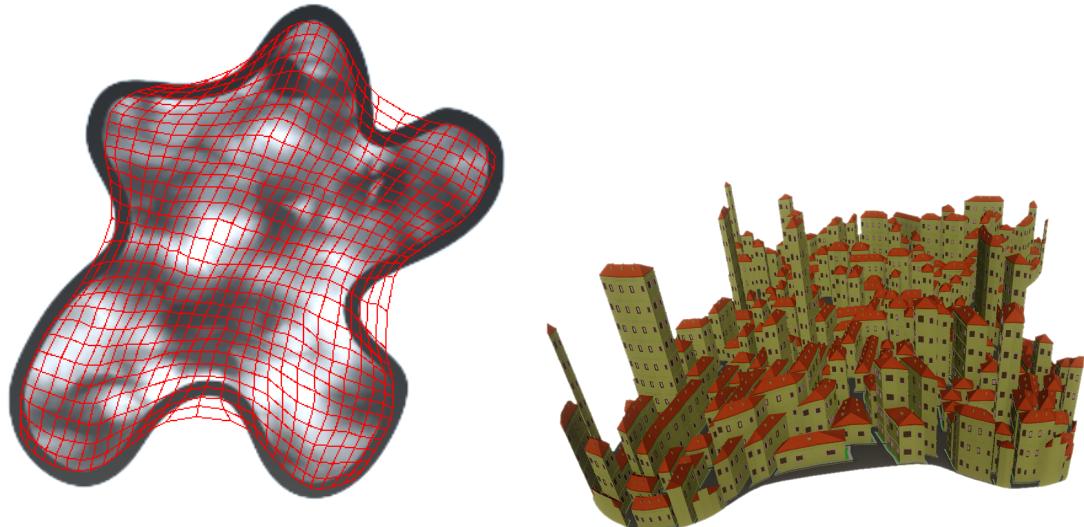

Figure 3.20: Placing nodes on a navigation mesh using graph-based WFC [26]

Another paper explores the use of a growing grid neural network to augment WFC [27]. Growing grid can be used to create irregular quadrilateral grids that fit a given input shape as in Figure 3.21(a). Here, gradients can be used to control grid density. WFC output can then be fit onto an irregular quadrilateral grid to create more interesting worlds as in Figure 3.21(b). This paper also found that players have higher self-confidence in navigating irregularly shaped maps and an increased ability to form mental maps of their environment.

(a) Growing grid creating an irregular quadrilateral grid fitting an input shape (b) Fitting WFC onto an irregular quadrilateral grid

Figure 3.21: Using growing grid and WFC to generate more complex worlds [27]

Very simple implementations may ignore symmetry when defining tile neighbours in the simple tiled method [28]. Instead, every neighbour for each direction of each tile is listed explicitly. While this keeps the code simple, it means that a huge amount of work is required when defining neighbours for complex tile sets, with high

chance of human error. What the original WFC implementation and several others do instead is to define a symmetry type for each tile. This means that much less data about the input has to be provided, lessening the work required and chance of human error. The original WFC implementation defines five symmetry types, which it applies to a variety of 2D images. Another paper instead defines nine symmetry types as in Table 3.1, which supports a greater variety of tile sets [24].

Name	Symmetry type	Initial tile's equivalent transformation number	New symmetry type after transformation
F	No symmetry	0	F/F/F/F/F/F/F/F
S	Centrosymmetric	0/2	S/S/S/S/S/S/S/S
T	Vertical axis symmetry	0/4	T/B/T/B/T/B/T/B
L	Counter-diagonal axis symmetry	0/5	L/Q/L/Q/Q/L/Q/L
B	Horizontal axis symmetry	0/6	B/T/B/T/B/T/B/T
Q	Main diagonal axis symmetry	0/7	Q/L/Q/L/L/Q/L/Q
I	Horizontal and vertical axis symmetry	0/2/4/6	I/I/I/I/I/I/I/I/I
/	Double diagonal axis symmetry	0/2/5/7	/'/'/'/'/'/'/'/'/'/
X	All 8 transforms are identical	0/1/2/3/4/5/6/7	X/X/X/X/X/X/X/X

Table 3.1: A symmetry dictionary proposed by [24]

3.3 Procedural Content Generation

3.3.1 Overview

Procedural Content Generation (PCG) describes the use of algorithms to pseudo-randomly generate content. In the context of video games, this randomisation is often used to provide players with variety that can make games more enjoyable to play multiple times. Procedural Content Generation can be used in many facets of video game development. One frequent use of PCG is in randomised level generation. For example, in exploration games such as Minecraft [29] and No Man's Sky [30], PCG is used to generate the player's world, offering virtually infinite locations to explore. Other uses include randomising enemy characteristics in Shadow of Mordor [31] and generating randomised weapons in Borderlands [32]. The book 'Procedural Content Generation in Games' [17] is a great resource to read more about PCG.

3.3.2 Current Applications and Research

A lot of modern PCG research looks into using AI and machine learning to generate content. Some current applications of machine learning are art, music and code generation as well as chatbots [33], text-to-3D synthesis [34] and even self-driving cars [35].

Applications like Stable Diffusion [36] can be used to create high quality text-to-image content, while others such as Magic3D [34] offers text-to-3D synthesis. In terms of text-to-text, ChatGPT [37] serves as a leading language model that can

be used to converse about any topic, while GitHub Copilot [38] can generate code snippets from user prompts.

In the context of games, machine learning is frequently used in areas like text, character model, texture, music and sound generation [39]. Languages such as the Video Game Description Language (VGDL) have even been used to generate entire games using AI [40], [41]. However, by themselves, such languages have limited expressiveness, making it difficult to create interesting games [40].

One paper [42] identifies that Generative Adversarial Networks (GANs) can also be used for image generation, but that it is difficult to incorporate constraints. As a solution, it proposes a Conditional Embedding Self-Attention Generative Adversarial Network (CESAGAN). This allows the embedding of a feature vector to the input, enabling the network to model non-local constraints. As a result, this produces higher quality outputs with fewer duplicates. In WFC, it is also difficult to enforce non-local constraints without additional modifications.

Another transforms 2D level design problems into Markov decision processes [43]. This aids reinforced learning to produce high quality output levels. It suggests this reinforced learning could be applied to self-play agents to improve the content generated through simulated playtesting. Three other papers similarly suggest that machine learning is useful for evaluating content through methods like simulated playtesting [39], [41], [44]. In the context of WFC, it might be useful to apply machine learning content evaluation and adjust the output to increase its quality.

One paper [44] also comments specifically on two limitations of PCG via machine learning. It states that the playability of output produced through machine learning is not guaranteed to be playable, but rather biased towards generating playable content through the input. The second limitation is that most machine learning has been applied to 2D content. Similarly, whether WFC output is playable or not is not always guaranteed but heavily depends on how the input is defined. Furthermore, the core WFC implementation and many of its offshoots only support 2D content generation [8]. As a result, both machine learning PCG and WFC require carefully tweaked input data and an output evaluator when applied to level generation.

Chapter 4

Requirements Specification

The following objectives were outlined in the Description, Objectives, Ethics and Resources (DOER) document at the start of the project. Primary objectives were chosen as core requirements of the project, with secondary objectives serving as additional goals if time allowed.

Primary Objectives

- Create a game that uses procedural level generation.
- Use novel PCG methods such as Wave Function Collapse.
- Extend on at least one PCG method.
- Use assets to give the game a full set of graphics and audio.

Secondary Objectives

- Make levels navigable by AI opponents.
- Allow customisation of level generation and other gameplay elements via an in-game menu.

Chapter 5

Software Engineering Process

5.1 Methodology

5.1.1 General Overview

The project was carried out with use of Agile methodologies. Weekly supervisor meetings were held, in which the past week's work would be evaluated. This was then contextualised within the overall time frame of the project. This critical analysis helped to identify and set goals for the next week and beyond. Agile development suited the nature of the project as the full progression of the project was not clear from the start. For example, initially it was planned to apply a Wave Function Collapse implementation directly and focus more on extending it to aid game design. However, while there were many implementations of WFC available online, many of them had poor documentation and did not work out of the box due to missing assets and errors, while others could not be applied to a 3D tile set. The official Wave Function Collapse GitHub contains links to other WFC implementations [8]. Four implementations investigate were the original implementation, two forks by Joseph Parker [45] and Maksim Priakhin [46] as well as a simplified implementation by Garnet Kane [28].

5.1.2 Semester One

The key areas of focus in the first semester were carrying out a literature review, setting objectives, reviewing ethics, designing the game and implementing the WFC algorithm. As described, the goal of the project was initially to extend upon an existing implementation of WFC. As this was unsuccessful, the focus changed to implementing an algorithm from scratch. After the core of the constraint solver was finished, WFC's lowest entropy cell selection and random weighted tile selection were added. The meeting notes for semester one are available in appendix section C.1.

5.1.3 Semester Two

The key areas of focus in the second semester were finishing the game and documenting the project in this report. The core generation had already been fully implemented, but assets still had to be created and put into the generator. Furthermore, extensions on the constraint solver, such as infinite modifying in blocks

and starting block constraints, had to be added to make levels infinite and playable. Additional work during the holidays involved studying infinite modifying in blocks, adding graphics filters and starting block modelling. A list of tasks was created during this time and extended during semester two. This list and the meeting notes for semester two are available in appendix sections [E](#) and [C.2](#) respectively.

5.2 Tools and Technologies

5.2.1 Unity (C#)

Unity was used as the game engine for development. This was chosen as Unity and its scripting API language C# have commonly been used for implementations of Wave Function Collapse, including the original WFC repository by Maxim Gumin [\[8\]](#). WFC has also been adapted to other engines such as Unreal Engine [\[47\]](#). Two issues that faced later development using Unity were its poor support for multithreading and importing .fbx models from Blender.

5.2.2 Blender

Blender was used to create tile models. Each model could be created and textured before being exported as .fbx files. These were then imported into Unity and unpacked. They could then be used as GameObjects and have any additional assets such as lights and audio sources attached.

5.2.3 GitHub

GitHub was used for version control. This was useful for comparing new and old code and tracking progress over time.

5.2.4 Document Management

Google Drive and Google Docs, both part of Google Workspace, were used to hold most documents relating to the project. This included a tasks document, game design document, weekly meeting notes, literature review research document and credits document for any external resources used. Furthermore, Overleaf was used to write up this report. These online platforms enabled work from multiple locations and more effective evaluation with the project supervisor as the latest versions of documents were always available.

Chapter 6

Ethics

There are no ethical considerations. All questions on the self-assessment form could be answered with “No”. This included the following declarations:

- The project did not use any secondary datasets.
- The project did not involve research with human subjects.
- No potential physical or psychological harm, discomfort or stress to researchers or participants was foreseeable.
- No conflicts of interest arose in the project.
- The project was not externally funded.
- The project did not involve the use of living animals.

Chapter 7

Design

7.1 Game Design

7.1.1 Premise

The premise of the game was inspired by the fictional concept of ‘the Backrooms’. These encompass an endless collection of ‘levels’, each a potentially infinite space with a unique theme centred around invoking a feeling of liminality. This was deemed a suitable theme to use for a game exploring novel procedural content generation techniques. The first level of the Backrooms, ‘Level Zero’, resembles an empty office-like space. Yellow wallpaper, light brown carpet and bright fluorescent lights combine to give it an unsettling monotone appearance and soundscape.

7.1.2 Gameplay

Player Controller

The player controller was taken from an online tutorial [48], [49]. Additionally, the ability to pick up and drop items was added. This allows the player to solve puzzles throughout the world.

Puzzles

The player must explore the backrooms in search of items spawned randomly with the level geometry.

7.2 Level Generation

7.2.1 Contextualising the Wave Function Collapse Algorithm

The Wave Function Collapse (WFC) algorithm can be viewed as an extension on the ideas presented by the Maintaining Arc Consistency 3 (MAC3) algorithm. What is referred to as a grid of cells with tile choices in Wave Function Collapse is analogous to a graph of variables / nodes with a domain of possible values. Constraints between variables can then be viewed as edges in an undirected graph as in Figure 7.1(a).

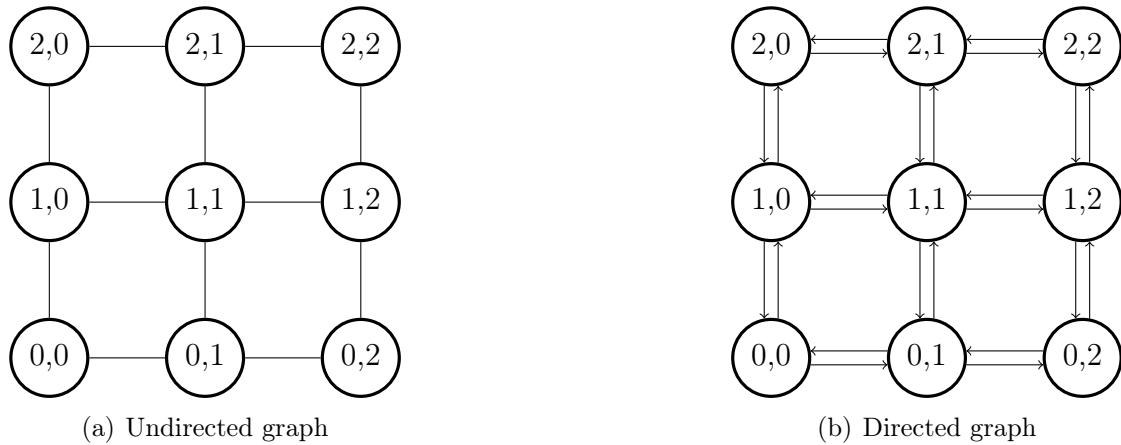

Figure 7.1: A 3×3 cell grid as an undirected and directed graph

7.2.2 Arcs

An edge in an undirected graph can alternatively be viewed as two opposite edges in a directed graph as in Figure 7.1(b). Arcs apply this concept to constraints, with each arc representing one of the two edges making up a constraint in the directed graph. For an arc to be locally arc consistent, all the values in the first variable's domain must be supported by at least one value in the second variable's domain.

For example, suppose the use of an extremely simple tile set with only cubes and empty tiles, where any tile choice is possible at the start. Furthermore, say that cubes can only have other cubes as neighbours and that empty tiles only have empty tiles as neighbours. This corresponds to Figure 7.2.

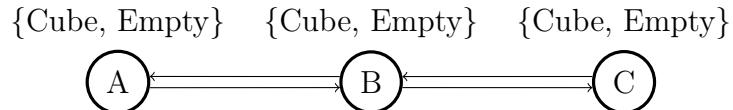

Figure 7.2: Example starting state, in which all arcs are consistent

Then, assume that node A is set to be a cube, removing the empty tile from its domain. Now, the arc $\langle A, B \rangle$ is consistent as B still has a cube as a support value. However, the arc $\langle B, A \rangle$ is no longer consistent since the empty tile does not have any support in A's domain, which only has the cube in it. This corresponds to Figure 7.3.

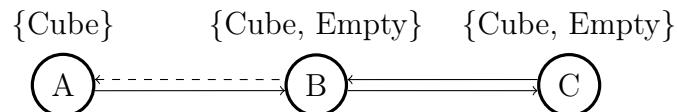

Figure 7.3: After assigning Cube to A, $\langle B, A \rangle$ is no longer consistent

7.2.3 AC3

The Arc Consistency 3 (AC3) algorithm enforces arc consistency in the grid of cells. The algorithm is given a queue of arcs to enforce arc consistency across. Each arc is

checked for support and unsupported domain values pruned. If any domain changes occur, then all arcs targeting the primary variable of the current arc are re-added to the queue. This is required as the domain change may have resulted in support for arcs to this variable being lost.

Back to the example, assigning Cube to A will trigger arc revision with all the arcs incident on A. In this case, this initialises the queue with arc $\langle B, A \rangle$. Checking the arc as in Figure 7.4 shows that B's Empty value is no longer supported by A.

1. Check arc $\langle B, A \rangle$:
 - (a) B's value Cube has support in A through its value Cube.
 - (b) B's value Empty does NOT have support in A! Remove it from the domain.

Figure 7.4: Revising arc $\langle B, A \rangle$

Performing this single revision leaves the graph in the state as shown in Figure 7.5. Revising $\langle B, A \rangle$ results in $\langle C, B \rangle$ becoming inconsistent, highlighting the importance of adding targeted arcs to the queue after a domain change. In this case, $\langle C, B \rangle$ must be added to the queue. $\langle A, B \rangle$ does not have to be added since the domain change happened while revising $\langle B, A \rangle$. This exploits the fact that arc support is bi-directional, meaning that if a value is supported on $\langle B, A \rangle$, then it must be supporting some value on arc $\langle A, B \rangle$.

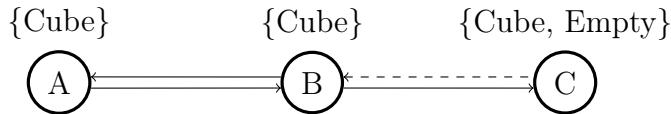

Figure 7.5: Revising $\langle B, A \rangle$ results in $\langle C, B \rangle$ becoming inconsistent

Revision of $\langle C, B \rangle$ proceeds similarly to revision of $\langle B, A \rangle$ as in Figure 7.4. Similarly, C's domain change from revision of $\langle C, B \rangle$ does not require re-checking of arc $\langle B, C \rangle$. After this, the queue of arcs to revise is empty and as such the consistency before assignment has been maintained. The state after revision is shown in Figure 7.6.

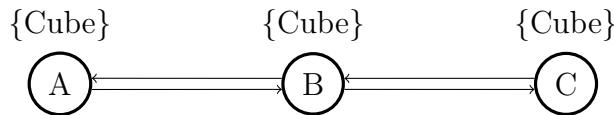

Figure 7.6: The graph after AC3 has been carried out

An additional property to note is that each node now only has one value in its domain. Given that each arc is consistent, this means that this is a valid solution to the original problem where each node could either be a cube or empty tile. In the context of WFC, this means that all cells have been collapsed with a valid tile choice and thus that a valid map has been generated.

7.2.4 MAC3

MAC3 uses AC3 to create a full constraint solving algorithm. To begin, AC3 is run with all arcs to ensure global arc consistency at the start. Then, a variable and value are chosen in an attempt to find a solution. This choice is like that done in the example shown previously in Figure 7.3. Arc consistency is then maintained by running AC3 with the all the arcs targeting the variable that had a value assigned as in Figure 7.4. This ensures that these arcs maintain local arc consistency. As global arc consistency was enforced at the start, maintaining local arc consistency after each assignment is enough to also maintain global arc consistency. If any variable assignments lead to a domain wipeout (an empty domain) when enforcing arc consistency, then backtracking can be performed and another value chosen. Once each variable only has one value left and all arcs are consistent, a solution has been found. If not stopped by a timeout, MAC3 will continue running until a solution has been found or all choices have been attempted, meaning that there is no solution.

7.2.5 Variable and Value Choice

The manner in which a variable and value are chosen can be implemented as desired. The most effective method often depends on the specific problem. A common method used in wave function collapse is lowest entropy cell selection together with weighted random tile selection.

Lowest Entropy Cell Selection

The lowest entropy method can be viewed as choosing the most constrained cell at each step as it takes into account the weight of each cell. This increases the chance to find a solution quickly as any contradictory assignments are reached faster and backtracked from with fewer steps. The weight of each tile is defined in the level editor and represents the target rate of occurrence of a tile in the generated level. Equation 7.1 shows the Shannon Entropy of a cell, which is lowest for cells with a small number of remaining tile choices of imbalanced weighting.

$$\text{Shannon Entropy} = S = \log\left(\sum \text{weight}\right) - \frac{\sum (\text{weight} \times \log(\text{weight}))}{\sum \text{weight}} \quad (7.1)$$

Weighted Random Tile Selection

Once a cell has been chosen, the tile choice is done by summing all tile weights and then choosing a random number within that range. This gives higher weight tiles a higher chance to be selected. If the tile choice did not include any randomness, then unplayable levels such as a completely empty level could be generated. This highlights the challenge in applying a simple constraint solver to level generation in a game. A level that satisfies all constraints for the solver does not necessarily translate to a good level. Some additional constraints could be added in, such as requiring a specific block in generated chunks. However, other constraints such as requiring a certain percentage of a specific block type in the entire level are harder to enforce effectively and efficiently. Such constraints can be encourage implicitly in generation, through features such as the weighted random tile selection. With this,

output is not guaranteed to satisfy block percentages, but instead strongly biased towards creating outputs that roughly match these constraints.

7.2.6 Infinite Modifying in Blocks

Infinite modifying in blocks works by splitting up generation into overlapping chunks, each of which are split into four layers. These layers are offset such that they do not interfere with each other. This can be used to ensure that generation is deterministic and optionally process each layer in parallel.

The algorithm is run layer by layer, finishing the layers of all active chunks before moving to the next layer. First, a layer is prepared. This involves calculating the area inside of the chunk that forms the layer and clearing all cells inside of it.

Second, the solver tries to find a solution for the layer. This takes into account adjacency information from the cells next to the layer. If a solution is not found, the layer is left as it was before. This is not an issue for most tile sets as single layer failures are hidden by other layers successfully generating.

Once each chunk has generated its first layer, the second layer is generated. This process is repeated until all layers have been generated.

7.3 Graphics

7.3.1 Models and Textures

The models with texturing for each tile were made in the software Blender using a YouTube video as a guide [50]. The tiles have distinct shapes, but share common wallpaper [51], ceiling tile [52] and carpet textures [53]. These textures are mapped so that they appear continuous when tiles are placed next to each other.

7.3.2 Camera Effects

To simulate the appearance of a video recorded onto a VHS tape, a range of camera effects were used. These are listed below.

7.3.3 Lighting Model

A deferred lighting model was used to light the level [54]. Unity's default lighting relies heavily on baked lighting to provide for high quality lighting. Baking lighting describes pre-calculating lighting before runtime. Textures can then be illuminated cheaply at runtime using this baking data to help give levels a realistic look.

As the project uses procedurally generated levels, it must heavily rely on realtime lighting instead. This describes lighting that is calculated at runtime as opposed to baked lighting. However, forward rendering (Unity's default rendering method) only allows for a limited number of realtime light sources to be rendered at once. Deferred lighting instead supports many realtime lights at the cost of less accurate lighting.

7.4 Audio

To give the game area an immersive soundscape, a collection of ambient effects and sound effects were used. Ambient effects are those sounds that are played equally at all times, while sound effects are those sounds that are placed inside of the environment. The most distinct sound effect of Level Zero of the Backrooms is the buzzing of the fluorescent lights. Each empty tile with a light is given an audio source that plays such a sound. Each light is given its own random offset so that the audio does not poorly overlap and cause constructive interference. For ambient sounds, a VHS sound and low droning are included. All audio assets were taken from freesound.org as this site offers sounds free for use in games.

7.5 Unity Editor and Tile Representation

The Unity Editor was used to provide a platform with which level designer could specify parameters for level generation. First, the level designer should attach the Level Generation Manager component to a unity game object. The designer may specify the size of chunks use in infinite modifying in blocks. Tiles are split into three different components across the entire specification to generation pipeline, with the tile set for generation specified in steps 1 and 2.

1. The level designer must first specify tiles by creating Unity game objects and then attaching a subclass of the Tile component to it. The Cube subclass exists for fully-symmetric tiles and the NonSymmetric subclass exists for all other tiles. The designer can then specify tile adjacencies by dragging other tile game objects into the neighbours arrays and specifying the desired rotation of the neighbouring tile. Base rotations of tiles should have their solid face at the back of the tile. The base rotation for corner tiles has the back of the corner on the left and back of the tile. Each game object should then be dragged into the tile set array of the level generator. Additionally, an empty tile must be specified directly.
2. After specifying tile adjacencies, the level designer should import FBX models to form a second set of game objects. These should be given a collider to avoid the player falling through the level. The designer can also add any additional components such as lights or audio sources. These model game objects can then be referenced in the matching tile script component. This tells the level generator to use the desired model for a given tile. The tile size specified in the level generator must match the size of the tile models in order for the generator to put them together properly.
3. Finally, the tile set that the level designer specified is converted from the designer-specified semi-explicit tile set to a fully-explicit tile set. The level generator takes each specified tile and rotates it in steps of 90 degrees, adjusting adjacency data to suit. This gives each possible rotation of a tile its own tile, hence the term fully-explicit. In effect, this enables the generation of maps without having to perform intermediate calculations on tile rotation, simplifying the algorithm at the cost of a larger tile set.

Chapter 8

Implementation

8.1 Cells

8.1.1 Cell Class

The Cell class contains integer coordinates, a set of possible tile options and a tile prefab game object. These variables allow the cell to be used in a grid for level generation. The set of tile options is initialised with the entire fully-explicit tile set, with tiles removed as WFC is run on a grid including the cell. Once the cell has been collapsed, the assigned tile is instantiated and a reference to it preserved in the tile prefab field.

8.1.2 CellArc Class

The CellArc class is used to represent arcs in the grid. It simply contains references to two cells and ensures that the arc is valid. This is done by comparing the x and y coordinates of the cells when creating the arc. An exception is thrown when the cells are not adjacent.

8.1.3 CellReference Class

The CellReference class simply contains a reference to a cell. By inheriting from MonoBehaviour, a cell reference can be attached to a tile. This allows a reference to the cell to be kept even after a layer has been spawned, allowing the cell information to be used in future generation.

8.2 Tiles

8.2.1 Rotation / Cardinality

Each spawned tile has a cardinality of either 0, 1, 2 or 3. This corresponds to rotations of 0, 90, 180 and 270 degrees respectively. This information is used to determine which combination of two tiles and their rotations fits together. For example, a single wall tile constituting part of a longer wall will require any adjacent wall tiles to be of the same cardinality. The valid cardinality of each tile neighbour must be specified by the level designer when specifying the tile set.

8.2.2 Tile Symmetry

To reduce the amount of adjacency data to be specified by the level designer as well as the chance for human error, the level generator includes functions to convert a semi-explicit tile set into a fully-explicit tile set. This fully-explicit tile set is created at the start of generation.

First, it is checked whether the empty tile was specified and is included in the semi-explicit tile set. After confirming this, the main conversion stage begins.

For each tile, a non-symmetric variant is created. First, a non-symmetric tile version of each tile in the tile set is instantiated. Second, an array for each possible tile rotation is created. This array is attached to the original tile to set explicit neighbours later. The instantiated tile is used as the base rotation and referenced in the array. From this base rotation tile, three other copies are created to obtain a variant for each possible rotation. These variants are also referenced in the array. For cube tiles, the base rotation tile can simply be referenced for each rotation instead of having to create additional copies.

For non-cube tiles, rotation variants must be created. Each new variant copies the previous one. This allows a loop to be used that always performs 90 degree steps. First, the tile is rotated by 90 degrees. Then, neighbour data and rotation arrays are swapped. This sets back neighbours as left neighbours, left neighbours as front neighbours and so on. Finally, the cardinality values of all neighbours are increased by one to mark the 90 degree rotation.

Once all the explicit variants have been generated, the neighbours of each tile can be set to the explicit variants. To do this, the array assigned to each tile containing all the explicit variants is used. For each neighbour of the explicit tile, the reference to the non-explicit neighbour is replaced by the explicit neighbour with the correct orientation.

8.2.3 Collapsing Cells

To collapse a tile into a cell, the tile's model is instantiated. Then, the model is set to follow the level generation manager's transform and has its local position set to the cell's world coordinates. Doing the placement like this ensures that the model lines up with the world grid while maintaining the correct scale and rotation. Finally, a box collider is added to the model, a second reference to the tile added to the cell and the model activated. The box collider helps with later generation as it can be detected when getting a previous cell's reference. The second reference ensures that the spawned tile can be recovered if generation of a layer fails.

8.3 Chunks

Chunks are defined by their own chunk coordinates, which are converted from world coordinates using the chunk size as a divisor. From this, each of the chunk's four layers can be defined. Layer one is aligned with the chunk's world coordinates, while layer two is offset by half a chunk in the x direction. Layer three is similarly offset by half a chunk in the y direction, while layer four is offset both in the x and y directions. Each layer is given its own layer spawner instance, which runs WFC on the portion of the chunk defined by the layer.

Each chunk has its own Random Number Generator (RNG), which is used by the layer spawners when making tile choices. The seed for the RNG is defined deterministically through the chunk's coordinates. The global level generation seed is added to allow generation of multiple levels while keeping determinism. This deterministic use of RNGs when spawning chunks is what allows the level generation manager to spawn chunks identically, even when unloading and loading a chunk again.

8.4 Level Generation Manager

8.4.1 Prerequisites

To start generation, the level designer must have defined a tile set for the generator to use. This must contain an empty tile and be convertible into an explicit tile set as detailed in Section 8.2.2.

8.4.2 Solver (Layer Spawners)

The MAC3 solver code is held in the LayerSpawner class. This matches up with the idea of layers and chunks modifying the world in an infinite set of blocks. To allow accurate placement of tiles in the world, a starting cell coordinate must be passed when initialising the layer spawner. Furthermore, a reference to the layer's parent chunk is kept in order to utilise its random number generator.

8.4.3 Grid Initialisation

First, a grid of cells is initialised. Additionally, a list of cells left to assign is initialised to simplify cell choices when solving. Padding on the layer size is used to include any previously collapsed cells. If any padded cells have not been collapsed, they are treated as empty tiles. This padding means that non-padded cells take into account full adjacency information. If the layer were not padded, then border cells would not have arc consistency with cells outside of the layer as these arcs would not be checked by the solver. The non-padding cells in the centre of the grid are refreshed by resetting each cell's tile options set to include all possible tiles. This allows each layer to re-generate its cells. In effect, this connects singular, overlapping layers into an infinite, continuous grid.

8.4.4 Dealing with an Infinite Grid

If every cell was stored in a global grid, then it would be trivially easy to get previously collapsed cells. This is unfeasible due to the requirement of letting the player navigate an infinite world. As such, once cells are collapsed, the grid used by the solver is discarded. Instead, the tile game object that was spawned in is given a 'CellReference' component. This simply stores a reference to the cell instance used by the grid. As each tile has its own collider and the coordinates for a given cell can be obtained from the world coordinates, Unity's 'Physics.OverlapBox' function can be used. This can obtain the collider of the tile given its world position, which can then be used to get the cell reference.

8.4.5 Setting up MAC3

With the layer's grid fully initialised, the main stage of the solver can now begin. First, a stack of state changes is initialised. This tracks changes to cells after each assignment by pushing a new state change to the stack. To make the grid globally arc consistent, the arc of each cell in the grid is generated. Subsequently, AC3 is run with this starting queue of cell arcs.

8.4.6 MAC3 Recursion

After this, the first iteration of a recursive implementation of the MAC3 algorithm is called. Pseudocode of this is given below. How each step works and its purpose is explained in more detail in subsections following the pseudocode.

1. If all cells have been assigned, return.
2. Choose a cell and tile to assign as in Section [7.2.5](#).
3. Enter a new state and assign the tile to the cell, pruning other tiles from its tile options set.
4. If the cell's tile options set changed, run AC3.
5. Recurse if AC3 was not run or there was no domain wipeout during AC3.
6. If all cells have been assigned, return.
7. We are now in the case that a domain wipeout must have occurred. Revert the state.
8. If the cell we tried to assign still has other options left, remove / ‘unassign’ the tile we tried from the options, run AC3 and recurse again.
9. If all cells have been assigned, return.
10. We are now in the case that all possible tile values for a cell led to a wipeout. This means that an earlier choice must be to blame. Restore the tile we tried both to assign and unassign and return.

Managing State Changes

To track state changes, each layer spawner holds a stack of state changes. After each time a new cell is chosen to be assigned, a new state is entered. A state change class is used that holds the cell being assigned and any domain changes occurring across the grid. Domain changes can happen to any cell and can consist of multiple tile changes, so a dictionary of cells to hash sets of tiles is used. To track a new state change, a new entry and hash set are added to the dictionary if required. After this, the hash set can be obtained from the dictionary through use of the cell and any tile changes added.

To revert a state, the domain changes dictionary is iterated through, with each cell having any removed tiles restored to its domain. Furthermore, the cell that was assigned in the state change is re-added to the list of cells left to assign.

Assigning and Unassigning a Tile to a Cell

Assigning a tile to a cell involves pruning all tiles except the one being assigned. These tiles are removed from the tile options set. Furthermore, each domain change is recorded in the current state changes. Finally, the assigned cell is removed from the list of cells left to assign. After this, AC3 can be run to maintain arc consistency.

Unassigning a tile to a cell first requires the state to be reverted. After this, the opposite choice is taken. This is done by pruning only the tile choice that was previously assigned. This demonstrates the 2-way branching nature of the implementation. Rather than exploring all possible tile values in one level of search, each tile value is either assigned or unassigned.

Visualising Recursion

The recursive MAC3 method can be visualised as consisting of three parts as in Figure 8.1.

1. Making a new assignment.
2. Making the opposite assignment (“unassignment”) after the first one failed.
3. Both assignments having failed.

Figure 8.1: The three parts of the recursive MAC3 method

The finishing state of the grid is checked both before making the new assignment and after each of the assignments. This ensures that the recursion is finished immediately after consistency has been enforced from an assignment and each cell only has one value left.

Chapter 9

Evaluation

9.1 Against Requirements Specification

9.1.1 Primary Objectives

Create a game that uses procedural level generation

The final project includes a very basic game in which the player can explore an infinite world generated through procedural level generation. The game is themed after ‘the Backrooms’, a fictional concept detailing an infinite expanse of ‘levels’. The first of these levels, ‘Level Zero’, is included in the game.

Use novel PCG methods such as Wave Function Collapse

Wave Function Collapse was studied thoroughly throughout the project. WFC was contextualised within theory of constraint programming and a simple-tiled implementation created using the MAC3 algorithm with lowest entropy cell and weighted random tile selection.

Extend on at least one PCG method

Standard Wave Function Collapse is finite in grid size and has increasing complexity with larger grid sizes. WFC was extended upon through the addition of the Infinite Modifying in Blocks algorithm. This helped generate output consistently, where standard WFC might require extensive backtracking in certain cases. Furthermore, it allowed WFC to be applied to generate an infinite world by generating many small, finite chunks as the player moves around in the world.

Use assets to give the game a full set of graphics and audio

A small set of models were created to serve as tiles for WFC. These match the design of the Backrooms through the use of online assets. Furthermore, a basic soundscape is created with some tiles given fluorescent lamp sound effects. Ambience sound played consistently throughout the game also add to this.

9.1.2 Secondary Objectives

Make levels navigable by AI opponents

No attempts were made to introduce AI opponents to the game.

Allow customisation of level generation and other gameplay elements via an in-game menu

The final game allows the user to set the seed of the level generator and includes an option to spawn with all the required items to solve puzzles more quickly.

9.2 Designer-facing Components

9.2.1 Editor Interface and Code Quality

The final project includes an interface for level designers to run the WFC implementation with their own tile set. Efforts were made to comment code clearly, which is something other WFC implementations miss. This is also an issue facing the original WFC implementation, which does not include any comments in its code [8].

9.2.2 Ease of Use

The level generation code includes exceptions that can tell the level designer what is incorrect with their setup. However, despite this additional guidance, the level generation manager interface can be confusing. Especially concepts such as cells vs tiles, tiles vs models and tile cardinality are likely to confuse users of the project's code. This problem is likely worsened since WFC is often treated as a black box by people from a range of backgrounds [11]. These users may not be experts in reading code and simply want to set up the generator with their own tile set. It is possible that these users are the likeliest to struggle with correctly setting up the level generation manager.

9.3 Player-facing Components

9.3.1 Gameplay

Players are able to explore an infinite map and solve simple puzzles to escape. While this may be interesting for a while, the experience has a significant issue with homogeneity. The low variety of models used means that the geometry of the level does not form many interesting structures. The lack of multiple levels also limits the amount of enjoyment players may get out of the game.

9.3.2 Performance

While the procedural level generation is functional, it suffers from a lack of optimisations that would make it more suitable to application for a video game. For example, chunk loading could be multi-threaded. However, implementation of this is difficult due to poor support by Unity. Furthermore, the use of Unity coroutines could be

explored to let chunk loading take place across multiple frames. This would avoid lag spikes, which can be very off-putting to players.

Chapter 10

Conclusion

The final project includes a simple game and designer tool for creating infinite worlds using Wave Function Collapse.

Implementing Wave Function Collapse and extending it with Infinite Modifying in Blocks presented a huge technical challenge. Ultimately, this detracted from work on the game itself.

Key areas of further development are identified in Figure 10.1.

- Solver optimisation: Add multi-threading and lazy loading across frames to avoid lag spikes. Also, rework code to more efficiently carry generation data across layers.
- Ease of use for designers: Make it simpler to specify a tile set for generation in the Unity Editor.
- Added variety to game: Add more models to the existing level and add additional levels.

Figure 10.1: Key areas of further development

Testing Summary

Appendix B

User Manual

Appendix C

Meeting Notes

C.1 Semester One Meeting Notes

Weeks 0 to 3

- Research and narrowing down project aims.
- DOER and ethics submissions.

Week 4 - 03.10.2023

- Create a design outline document.
- Try to adapt one of the WFC implementations to 3D.
 - <https://github.com/GarnetKane99/WaveFunctionCollapse>
 - Up, down, right, left, front, back neighbours.
 - Each prefab in the neighbours array should have a weighting too. Use an entropy calculation.
- Get a simple, one-room playable demo.

Week 5 - 10.10.2023

- No meeting ILW.
- Adapt research into a draft context / literature review for the final report (see email for lit rev guide).
- Get WFC working with weights by the next meeting.

Week 7 - 24.10.2023

- Try to finish literature and make an introduction to WFC in the report.
- Implement your own WFC.

Week 8 - 31.10.2023

- Continue working on WFC algorithm.

Week 9 - 10.11.2023

- Fix last bugs with MAC.
- Either get in symmetries or give each neighbour data explicitly for now to get generation working properly.
- Lowest entropy.

Week 10 - 17.11.2023

- Implement weighting into the algorithm.
- Have another look at what is meant by entropy.
- Make notes on the directional artefacts (probably a result from overfitting / tileset neighbour bias).

Week 11 - 24.11.2023

- Visual debugger to help with artefacts (diagonal, edge only shapes...)
- Refocus a bit on the game element (texturing, filter, ...)
- Extra: Infinite modifying in blocks, sub-wfc.

C.2 Semester Two Meeting Notes

Week 1 - 17.01.2024

- Goal block
- Have player start in middle of grid with empty blocks around at start of generation.
- Look more into the lighting. Replace placeholder carpet and roof. Check performance of tiling roof.

Week 2 - 24.01.2024

- Main Goals:
 - Continue working towards chunk generation.
 - * Let chunks that are separately generated overlap information.
 - Chunks have trouble generating. Maybe the overlap method is not fully correct. Think about overlap size and simply getting information vs delete some part.
 - Infinite modifying in blocks with good chunk sizes might help without backtracking.
 - * Allow backtracking for chunks.
 - Script goal to let player win.
 - * Detect when the player touches the goal.
 - * Show a message and go back to the menu / teleport the player somewhere else.

- Extra:
 - Add in a mini sub-region to test (i.e freezer).
 - Think about making a variant for empty vs empty light.
 - Graphics improvements:
 - * Fog / render distance if needed later.
 - Adjusted fog colour.
 - Should anything else be adjusted? For now, no render distance cust. needed.
 - * Make vhs effect screen space rather than plane.
 - Seems to be difficult to overlay onto the render texture without more cameras.
 - * Skybox lighting for ambient light.
 - * Balance light settings and bloom a bit more.
 - Audio improvements:
 - * Script the lights to have random offset.
 - Should probably also replace the buzz with something that doesn't tick.
 - * Add VHS SFX to the player.

Week 3 - 31.01.2024

- Only discussed progress per email.
- Implement infinite modifying in blocks for next week.

Week 4 - 07.02.2024

- Do report writing.
- Polish game and finish any 90% implemented features.
- ((Test performance of 2D grid vs linear grid. Might be changed automatically by C#. Probably done automatically))

Week 5 - 15.02.2024

- Focussing more on other projects at the moment.
- Tried to do parallelisation, but it wasn't simple. Focus on other things first.
 - Generate the level as the player moves about.
- Continue report writing when able.

Week 6 - 22.02.2024

- Very busy with other courseworks.
- Continue the report in chunks over the break.

Appendix D

Design Document

Outline

- Backrooms-style game using Wave Function Collapse (WFC) to infinitely generate rooms.
- Different tilesets can be used to generate different levels.

Generator

- First generate a fixed size level of a few tiles. Later, generate in chunks (modifying in infinite blocks) to support infinite generation as well as with more tiles.
- Generate geometry for each level. Give “doors” a weighting to go into another sub-level.
- Is it worth integrating some more traditional methods? Traditional generators may work better for rooms. Something more random like WFC might work better for Backrooms.

Modules / Blocks

- Each a 1x1 tile, Empyrion style block with adjacency constraints and weighting (how?) for each.
 - Full
 - * Floor (full with carpet on top)
 - * Ceiling (full with ceiling on bottom)
 - * Could do all three in one block type? Or maybe use texture variations somehow.
 - Wall (half block)
 - * Crouch hole (rotated wall)
 - Corner (half)
 - Corner (quarter)

- Thin Wall (quarter)
- Corner pillar (half)
- Corner pillar (quarter)
- Ceiling tiles
 - * A single tile consisting of multiple tiles (2x2?). Above empty, give each sub-tile a chance of being emissive.
- Empty
- Centre pillar
- Miscellaneous half block variants that fit other normal blocks for variety.

Regions / Structure

- Make a “door” tile that is a floor tile with adjacencies that connect several sublevels.
- Is there a better way of doing this that maintains modularity?
- How might room structures be made while maintaining modularity?
 - Not needed for some areas of the backrooms (i.e. starting area) as they are not well structured.
- Use a density noise map that defines how empty or full an area of the map is. Helps give natural variety.
 - Can also apply noise to lights and grunge for textures.

Goal

- Collect key items across sublevels (and levels?) to unlock new areas / objectives (Monstrum escape route style).

Appendix E

Holiday and Semester Two Task List

- Algorithm
 - Make the algorithm visual (intermediate steps)
 - Give control of generation to the player via keyboard when debugging.
 - Infinite modifying in blocks
 - * Think about how this will affect modularity. Will implementing this mean changes to the base algorithm will be harder to make? Or will this just always work on top? It will probably work separately.
 - Sub-WFC
 - Generate block variants for symmetries from the initial block.
- Audio
 - Get ambience sounds
 - Footstep sounds
 - Audio filter
- Game
 - Objectives
 - * Spawn items for objectives
 - * Spawn key locations among random generation
 - Set up player in Unity to start in the middle of the maze
 - Make a menu screen to start the game.
- Graphics
 - Textures for each block
 - * Got a low res wallpaper texture and simple colour for rims. Should help performance.
 - * In the future, use AI art for some textures? (Just a possibility)
 - Filters for the camera
 - * First round of basic effects. Could probably be enhanced in quality later.

- Graphics for floor and lights.
 - * Have a flat texture for the whole map? Or break it into block chunks too? Performance?
 - * Get proper lighting in that is also performant.
- Report
 - Break into sections.
 - * Game design, algorithms, discuss different options and things tried, audio and graphics...
